*Additional index words.* bioassay, growth retardant, sucrose, tissue culture

**Abstract.** The gibberellin biosynthesis inhibitor, ancymidol, was used during micropropagation of *Hosta* 'Blue Vision'. Shoot growth and bud division was monitored every 2 weeks over an 8-week period in media containing 1  $\mu\text{M}$  benzyladenine (BA) and various levels of ancymidol (0, 0.1, 0.32, 1 and 3.2  $\mu\text{M}$ ). Ancymidol prolonged bud division from 2 to 6 weeks and increased the total number of buds produced. Shoots grown in medium containing ancymidol had greater fresh weight, shorter-broader leaves and less dry weight than those grown without ancymidol. Reduced dry weight of buds grown in the presence of ancymidol was correlated to the depletion of sugars in the medium. A bioassay using 'Saturn' tall rice revealed that ancymidol was active for the entire 8-week culture period.

*Hosta* is currently among the most valuable ornamental crops in the United States (U.S. Department of Agriculture, National Agricultural Service, 1998) and often propagated commercially through tissue culture (Zimmerman, 1996). Maximum bud formation during the multiplication stage (commonly referred to as Stage II) is an important component of laboratory efficiency and is optimized in tissue culture by altering the concentrations of plant growth regulators in the media. Cytokinins are known to increase cell division, break apical dominance and effect source-sink relations (D'Agostino and Kieber, 1999). Benzyladenine (BA) is effective in inducing crown divisions, both in vitro (Hartmann et al., 1997) and in field production (Garner et al., 1998) of *hosta* offsets.

Gibberellin inhibitors, including ancymidol and paclobutrazol, were found useful in micropropagation by reducing stem and leaf elongation and producing shoots better acclimatized for field conditions (Ziv, 1995). Ancymidol affects gibberellin synthesis by inhibiting oxidative steps in the biosynthesis of *ent*-kaurene (a gibberellin precursor), most likely through interactions with the active site of the enzyme (Sugavanam, 1984). Ancymidol also increased both starch and soluble sugar concentrations in leaves of liquid cultured *Narcissus* (Chen and Ziv, 2001, 2003). Greater starch concentrations at meristematic centers preceded enhanced shoot proliferation. Repeated aseptic handling of long, floppy plantlets wet with sugar-rich liquid media during multiplication (stage II), was made easier when plantlet size was reduced by ancymidol and BA in the ornamental elephant ears, *Alocasia* and *Colocasia* (Adelberg and

Toler, 2004). Shorter, thicker microcuttings with reduced leaf area are more resilient to water loss during acclimatization (Ziv, 1994).

Commercial micropropagation uses semi-solid agar, despite findings that liquid medium induces more rapid bud division and larger plants due, in part, to greater sugar uptake from liquid medium (Adelberg, 2005a; Adelberg and Toler, 2004). *Hosta* plantlets produced in liquid medium have increased dry weight and endogenous soluble solids concentrations linearly related to media sucrose levels over the 1% to 7% w/v range (Gollagunta et al., 2004). *Hosta* plants grown in liquid medium have greater dry weight and faster root growth in the outdoor nursery compared to those reared in agar-solidified medium (Adelberg et al., 2000).

At high plant densities (330 explants/L) sucrose depletion from liquid media was found to limit growth of elephant ears (Adelberg and Toler, 2004). Plants on agar at similar density did not grow as large or deplete sugar. A balance must exist between plant biomass and the mass of sugar supplied from the medium. The objective of this study was to use various concentrations of ancymidol over eight weeks in stage II culture medium to retard leaf-elongation during bud division while monitoring sugar uptake.

## Materials and Methods

**Plant material.** *Hosta* 'Blue Vision' explants were provided by Southern Sun Inc., Norris SC. Four explants with about two buds each were placed in 180-mL jars (Gerber Foods, Asheville, N.C.) containing 35 mL of liquid tissue culture media and placed in on a continuous orbital shaker 100 rpm shelf with 25 to 35  $\mu\text{mol}\cdot\text{s}^{-1}\cdot\text{m}^{-2}$  PAR provided by cool white fluorescent tubes. The photoperiod was 16 hours and temperature was maintained at  $22 \pm 1$  °C.

**Liquid media.** The base medium consisted of a modified Murashige and Skoog media (MS) (Murashige and Skoog, 1962) containing addition of 170  $\text{mg}\cdot\text{L}^{-1}$  sodium phosphate, increased  $\text{CuSO}_4\cdot 5\text{H}_2\text{O}$  concentration to 25  $\text{mg}\cdot\text{L}^{-1}$ , and excluding potassium iodide (KI). Organic constituents of the medium included

(per liter) 0.5 mL MS vitamin solution (Sigma M-3900), 92 mg adenine hemisulfate, 30 g sucrose and 1  $\mu\text{M}$  benzyladenine. Ancymidol was added base medium to achieve concentrations of 0, 0.1, 0.32, 1.0, or 3.2  $\mu\text{M}$ . Media pH was adjusted to 5.5 before being dispensed into culture vessels.

**Experimental design.** A completely randomized design was used with four single-jar replications per treatment per harvest time. The number of buds produced per vessel, tissue fresh weight, tissue dry weight and length to width ratio for the largest leaf were recorded every 2 weeks over an 8-week period. Residual medium content was measured with a BRUX refractometer. Data were subjected to analysis of variance and linear models were fit to least squares at  $P = 0.05$  (JMP version 3.2.6, SAS Inst., Cary, N.C.). Bud data was transformed with a square root conversion. For clarity of presentation, only data for 0, 0.32  $\mu\text{M}$  and 3.2  $\mu\text{M}$  ancymidol concentrations were presented for weeks 2 through 8.

**Bioassay for media ancymidol concentration.** Seed of 'Saturn' tall rice (provided by Richard Dunand, Louisiana State University Rice Research Station) were surfaced sterilized in 200 mL of 0.525 % NaOCl (provided as dilute commercial bleach) with a drop of Tween 20 for 10 min followed by two rinses with sterile, distilled water. Disinfested seeds were pregerminated on moistened filter paper in a 9-cm petri dish for 4 d at 30 °C in darkness. Imbibed seeds were placed onto 18-cm-diameter Sorbarod (Ilacon Industries, Ltd., U.K.) paper plugs, nine per vessel (Magenta Corp., Chicago, Ill.), saturated with 18 mL of media from the culture jars. Seedlings were allowed to grow for 6 d under cool-white fluorescent light at 30 °C before measuring the second leaf sheath length. The shortest and longest leaf sheath lengths were omitted and an average of seven leaf sheaths per culture vessel was recorded.

## Results and Discussion

Fewer buds were produced in medium without ancymidol (Fig. 1a). In fact the 15 buds per vessel were present after the first 2 weeks of culture at which time bud division had ceased. Addition of 3.2  $\mu\text{M}$  ancymidol to the culture medium stimulated the formation of shoot buds with an optimum of about 50 buds per vessel harvested 6 weeks after initiation. Numbers of buds increased with higher concentrations of ancymidol. By week 8, there was linear relation between number of buds and ancymidol concentration ( $R^2 = 0.29$ ,  $P < 0.0137$ ).

Most of the fresh weight gain occurred in weeks 2 through 6 (Fig. 1b). The presence of ancymidol increased fresh weight by about 25%. Dry weight, however, followed different trends (Fig. 1c). Dry weight increased over the entire 8 weeks of culture only in the absence of ancymidol. In the presence of ancymidol, dry weight gain slowed by week 4 and ceased by week 6. By the week 8, there was an inverse relation between ancymidol concentration and dry weight ( $R^2 = 0.39$ ,  $P < 0.0031$ ), where the higher ancymidol concentrations had the lower dry weights.

Received for publication 4 June 2004. Accepted for publication 2 Nov. 2004. This work is publication no. 4883 of the SC Agriculture and Forestry Research Service.

Fig. 1. The effect of ancyamidol on (a) the total number of buds produced per culture vessel; (b) explant fresh weight (g) per culture vessel; and (c) explant dry weight (g) per culture vessel during an 8-week culture cycle.

Relative dry weight (dry weight/fresh weight) is often used as an index of shoot quality in propagation, and this ratio was affected by ancyamidol (Fig. 2a). Relative dry weights were 8% to 9% (95% CI) throughout the entire 8-week culture cycle in medium without ancyamidol. In presence of ancyamidol there was a significant reduction in relative dry weight during weeks 2 through 6, the period of most rapid growth and development. Sugar

residual in media also decreased sharply during this period of most rapid growth (Fig. 2b). In media containing ancyamidol, sugar concentration was nil during weeks 6 and 8, when dry matter accumulation had ceased.

Dry matter accumulation is driven by the difference between sugar levels in the medium and the plant, whereas fresh weight gain is related to the plants' relative water content and the water content of the medium (Ibaraki

and Kurata, 1998). When media sugar residuals becomes depleted at high plant densities, tissues grow by taking on more water relative to soluble solids. Residual sugar concentration was directly related to the relative dry weight of plantlets during the 8-week sampling period ( $R^2 = 0.69$ ,  $P < 0.0001$ ). Sugar concentration was also correlated to relative dry weight in several tissue-cultured species including ornamental elephant ears (Adelberg and Toler, 2004), venus flytrap and watermelon (Adelberg, 2005b).

Hosta 'Blue Vision' has elongated lanceolate leaves. All concentrations of ancyamidol (0.1 to 3.2  $\mu\text{M}$ ) made the leaves smaller, shorter and wider than plantlets without ancyamidol (data not shown). A bioassay with the tall rice variety, 'Saturn', revealed no change in ancyamidol activity throughout the 8-week cycle (data not shown). The objective of stage II is to multiply shoot buds and leaves are often cut away and discarded during subculture. The use of ancyamidol as a growth regulator in the presence of BA shifts growth from the elongated leaf blade to the shoot buds. Smaller, denser clumps of shoot bud clusters are easier to manually transfer (Adelberg and Toler, 2004) and also more amenable to mechanical cutting (Alper et al., 1994; Ziv et al., 1994).

Interactions between ancyamidol concentrations and media sucrose levels were observed for promotion of asparagus somatic embryos (Li and Wolyn, 1997). *Narcissus* leaf scales in liquid cultures have higher levels of soluble sugars and starch, prior to the formation of shoot bud clusters (Chen and Ziv, 2001, 2003). Ancyamidol suppressed leaf elongation and increased the duration of bud multiplication and growth. The concomitant depletion of sugar lowered the dry weight ratio. The use of ancyamidol during micropropagation should include observations of sugar adequacy to maintain sufficient dry matter content.
